## The Weirdest People in the World

---

*How representative are experimental findings from American university students?  
What do we really know about human psychology?*

### Short Abstract

Broad claims about human psychology and behavior based on narrow samples from Western societies are regularly published. Are such species-generalizing claims justified? This review suggests not only substantial variability in experimental results across populations in basic domains, but that standard subjects are unusual compared with the rest of the species—outliers. The domains reviewed include visual perception, fairness, spatial reasoning, moral reasoning, thinking-styles, and self-concepts. This suggests (1) caution in addressing questions of *human* nature from this slice of humanity, and (2) that understanding human psychology will require broader subject pools. We close by proposing ways to address these challenges.

### Long Abstract

Behavioral scientists routinely publish broad claims about human psychology, cognition, and behavior in the world's top journals based on samples drawn entirely from highly educated segments of Western societies. Researchers—often implicitly—assume that either there is little variation across human populations, or that these “standard subjects” are as representative of the species as any other. Are these assumptions justified? Here, our review of the comparative database from across the behavioral sciences suggests both that there is substantial variability in experimental results across populations and that standard subjects are particularly unusual compared with the rest of the species—frequent outliers. The domains reviewed include visual perception, fairness, cooperation, spatial reasoning, categorization and inferential induction, moral reasoning, reasoning styles, self-concepts and related motivations, and the heritability of IQ. **The comparative findings suggest that members of Western, educated, industrialized, rich, and democratic societies, including young children, are among the least representative populations one could find for generalizing about humans.** Many of these findings involve domains that are associated with fundamental aspects of psychology, motivation, or behavior—hence, there are no obvious *a priori* grounds for claiming that a particular behavioral phenomenon is universal based on sampling from a single subpopulation. Overall, these empirical patterns suggests that we need to be less cavalier in addressing questions of *human* nature on the basis of data drawn from this particularly thin, and rather unusual, slice of humanity. We close by proposing ways to structurally re-organize the behavioral sciences to best tackle these challenges.

Keywords: population variability, experiments, universals, human nature, cross-cultural research, generalizability, research methods

In the tropical forests of New Guinea the Etoro believe that for a boy to achieve manhood he must ingest the semen of his elders. This is accomplished through ritualized rites of passage that require young male initiates to fellate a senior member (Herdt 1984, Kelley 1980). In contrast, the nearby Kaluli maintain that male initiation is only properly done by ritually delivering the semen through the initiate's anus, *not* his mouth. The Etoro revile these Kaluli practices, finding them disgusting. To become a man in these societies, and eventually take a wife, every boy undergoes these initiations.

Such in-depth studies of "exotic" societies, historically the province of anthropology, are crucial for understanding human behavioral variation. However, this paper is not about these peoples. It's about another exotic group: people from Western, Educated, Industrialized, Rich, and Democratic (WEIRD<sup>1</sup>) societies. In particular, it's about the Western, and more specifically American, undergraduates who form the bulk of the database in the experimental branches of psychology, cognitive science, and economics, as well as allied fields (labeled the "behavioral sciences"). Given that scientific knowledge about human psychology is largely based on findings from this population, we ask just how representative are these typical subjects in light of the available comparative database. How justified are researchers in assuming a species-level generality of their findings? Here, we review the evidence regarding how WEIRD people compare to other populations.

To pursue this we constructed an empirical review by looking first for studies involving large-scale comparative experimentation on important psychological or behavioral variables. Although such larger-scale studies are highly informative, they are rather rare, especially when compared to the frequency of species-generalizing claims. When such studies were absent we have relied on large assemblies of studies comparing 2 or 3 populations, and, when available, on meta-analyses.

Of course, researchers do not implicitly assume psychological or motivational universality with everything they study. The present review does not address those phenomena assessed by individual difference measures or for which the guiding assumption in the research is variability among populations. Phenomena such as personal values, emotional expressiveness, and personality traits are expected *a priori* to vary across individuals, and by extension, societies. Indeed, the goal of much research on these topics is to identify the ways that people and societies differ from one another on these with regard to these phenomena. For example, a number of large projects have sought to map out the world on dimensions such as values (Hofstede 2001, Inglehart et al. 1998, Schwartz & Bilsky 1990), personality traits, (e.g., McCrae et al. 2005, Schmitt et al. 2007), and levels of happiness, (e.g., Diener et al. 1995). Similarly, we avoid the vast psychopathology literature, which finds much evidence for both population-level variability and universality in psychological pathologies (Kleinman 1988, Tseng 2001), because

this work focuses on individual-level (and unusual) variations in psychological functioning. Instead, we restrict our exploration to those constructs which have largely been assumed, at least until recently, to be *de facto* psychological universals.

Finally, we also do not address societal-level behavioral universals, or claims thereof, related to phenomena like dancing, fire-making, cooking, kinship, body adornment, play, trade, and grammar for two reasons. First, at this surface level alone such phenomena do not make specific claim about universal underlying psychological or motivational processes. Second, systematic, quantitative, comparative data based on individual-level measures is typically lacking for these domains.

Our examination of the representativeness of WEIRD subjects is necessarily restricted to the rather limited database currently available. We have organized our presentation into a series of telescoping contrasts showing, at each level of contrast, how WEIRD people measure up relative to the other available reference populations. Our first contrast compares people from modern industrialized societies with those from small-scale societies. Our second telescoping stage contrasts people from Western societies with those from non-Western industrialized societies. Next, we contrast Americans with people from other Western societies. Finally, we contrast university-educated Americans with non-university educated Americans, or university students with non-student adults, depending on the available data. At each level we discuss behavioral and psychological phenomena for which there are available comparative data, and we assess how WEIRD people compare with other samples.

We emphasize that our presentation of telescoping contrasts is only a rhetorical approach guided by the nature of the available data. It should *not* be taken as capturing any uni-dimensional continuum, or suggesting any single theoretical explanation for the variation. Throughout this paper we take no position regarding the substantive origins of the observed differences between populations. While many of the differences are probably cultural in nature in that they were socially transmitted as a consequence of growing up in a particular social group (Boyd & Richerson 1985, Nisbett et al. 2001), other differences are likely environmental and represent some form of non-cultural phenotypic plasticity, which may be developmental or facultative, as well as either adaptive or maladaptive (Gangestad et al. 2006, Tooby & Cosmides 1992). Other subpopulation differences could arise from genetic variation, as observed for lactose processing into adulthood (e.g., Beja-Pereira et al., 2003). Regardless of the reasons underlying these population differences, our concern is whether researchers can reasonably generalize from WEIRD samples to humanity at large.

Many radical versions of cultural relativity deny any shared commonalities in human psychologies across populations. To the contrary, we expect humans from all societies to share, and probably share substantially, basic aspects of cognition, motivation, and behavior. As

researchers who see much value in applying evolutionary thinking to psychology and behavior, we have little doubt that if a full accounting were taken across all domains among peoples past and present, that the number of similarities would indeed be large, as much ethnographic work suggests (e.g., Brown 1991)—ultimately, of course, this is an empirical question. Thus, our thesis is *not* that humans share few basic psychological properties or processes; rather we question our current ability to distinguish these reliably developing aspects of human psychology from more developmentally, culturally, or environmentally contingent aspects of our psychology given the disproportionate reliance on WEIRD subjects. Our aim here, then, is to inspire efforts to place knowledge of such universal features of psychology on a firmer footing by empirically addressing, rather than dismissing or ignoring, questions of population variability.

## 1 Background

Before commencing with our telescoping contrasts, we first discuss two observations regarding the existing literature: (1) the database in the behavioral sciences is drawn from an extremely narrow slice of human diversity; and (2) behavioral scientists routinely assume, at least implicitly, that their findings from this narrow slice generalize to the species.

### 1.1 The Behavioral Sciences Database is Narrow

Who are the people studied in behavioral science research? A recent analysis of the top journals in six sub-disciplines of Psychology from 2003-2007 revealed that 68% of subjects came from the US, and a full 96% of subjects were from Western industrialized countries, specifically North America, Europe, Australia, and Israel (Arnett 2008). The make-up of these samples appears to largely reflect the country of residence of the authors, as 73% of first authors were at American universities, and 99% were at universities in Western countries. This means that 96% of psychological samples come from countries with only 12% of the world's population. Put another way, a randomly selected American is 300 times more likely to be a research participant in a study in one of these journals than is a randomly selected person from outside of the West.

Even within the West, however, the typical sampling method for psychological studies is far from representative. In the *Journal of Personality and Social Psychology*, the premier journal in social psychology—the sub-discipline of psychology that should (arguably) be the most attentive to questions about the subjects' backgrounds—67% of the American samples (and 80% of the samples from other countries) were composed solely of undergraduates in psychology courses (Arnett 2008). Furthermore, this tendency to rely on undergraduates as samples has not decreased over time (Peterson 2001, Wintre et al. 2001). Such studies are thus sampling from a rather limited subpopulation within each country.

Perhaps the dominance of American authors in psychology publications just reflects that American universities have the resources to attract the best international researchers, and that similar tendencies exist in other fields. However, psychology is a distinct outlier here: 70% of all psychology citations come from the US—a larger percentage than any of the other 19 sciences that were compared in one extensive international survey (May 1997). In chemistry, by contrast, the percentage of citations that come from the U.S. is only 37%. It seems problematic that the discipline in which there are the strongest theoretical reasons to anticipate population-level variation is precisely the discipline in which the American bias for research is most extreme.

Beyond psychology, the subject pools of experimental economics and decision science are not much more diverse, still largely dominated by Western undergraduates. However, economists are (1) establishing nationally representative experimental samples in Europe, (2) apply experimental methods in developing countries, (3) creating university-wide subject recruiting rather than discipline-specific subject pools, and (4) targeting specific samples of non-student subjects (Bellemare et al. 2008, Bellemare & Kroger 2007, Fehr et al. 2002, Guth et al. 2003, Harrison et al. 2002, List 2004).

In sum, the available database does not reflect the full breadth of human diversity. Rather, we have largely been studying the nature of WEIRD people, a certainly narrow and potentially peculiar subpopulation.

## 1.2 Researchers Often Assume their Findings are Universal

Sampling from a thin slice of humanity would be less problematic if researchers confined their interpretations to the populations from which they sampled. However, despite their narrow samples, behavioral scientists often are interested in drawing inferences about the *human* mind. This inferential step is rarely challenged or defended—with some important exceptions (e.g., Medin & Atran 2004, Rozin 2001, Witkin & Berry 1975)—despite the lack of any general effort to assess how well results from WEIRD samples generalize to the species. This lack of epistemic vigilance underscores the prevalent, though implicit, assumption that the findings one derives from a particular sample will generalize broadly; one adult human sample is pretty much the same as the next.

The leading scientific journals and university textbooks consistently publish research findings that generalize to “humans” or “people” based on research done entirely with WEIRD undergraduates. In top journals such as *Nature* and *Science* researchers frequently extend their findings from undergraduates to the species—often declaring this generalization in their titles. These contributions typically lack even a cautionary footnote about these inferential extensions.

In psychology, much of this generalization is implicit. A typical article does not claim to be discussing “humans” but will rather simply describe a decision bias, psychological process, set of correlations, etc., without discussing issues of generalizability, though findings are often linked to “people.” Commonly, there will be no mention of any demographic information about the participants aside from their age and gender. Though, in recent years there is a trend to qualify some findings with disclaimers such as “at least within Western culture,” there remains a robust tendency to generalize to the species. Arnett (2008) notes that psychologists would surely bristle if journals were renamed to more accurately reflect the nature of their samples (e.g., *Journal of Personality and Social Psychology of American Undergraduate Psychology Students*). They would bristle, presumably, because they believe that their findings would broadly generalize. Of course, there are important exceptions to this general tendency as some researchers have assembled a broad database to provide evidence for universality (e.g., Buss 1989, Daly & Wilson 1988, Tracy & Matsumoto 2008).

When is it safe to generalize from a narrow sample to the species? First, if one had good empirical reasons to believe that little variability existed across diverse populations in a particular domain it would be reasonable to tentatively infer universal processes from a single subpopulation. Second, one could make an argument that as long as one’s samples were drawn from near the center of the human distribution then it would not be overly problematic to generalize across the distribution more broadly—at least the inferred pattern would be in the vicinity of the central tendency of our species. Below, with these assumptions in mind, we review the evidence for the representativeness of findings from WEIRD people.

## 2 Contrast 1: Industrialized Societies vs. Small-Scale Societies

Our theoretical perspective, which is informed by evolutionary thinking, leads us to suspect that many aspects of people’s psychological repertoire are universal. However, the current empirical foundations for our suspicions are rather weak because the database of comparative studies that include small-scale societies is scant, despite the obvious importance of such societies in understanding both the evolutionary history of our species and the potential impact of diverse environments on our psychology. Here we first discuss the evidence for differences between populations drawn from industrialized and small-scale societies in some seemingly basic psychological domains, and follow this with research indicating universal patterns across this divide.

### 2.1 Visual Perception

Many readers may suspect that tasks involving “low-level” or “basic” cognitive processes such as vision will not vary much across the human spectrum (Fodor 1983). However, in the 1960s an interdisciplinary team of anthropologists and psychologists systematically gathered data on the

susceptibility of both children and adults from a wide range of human societies to five “standard illusions” (Segall et al. 1966). Here we highlight the comparative findings on the famed Mueller-Lyer illusion, because of this illusion’s importance in textbooks, and its prominent role as Fodor’s indisputable example of “cognitive impenetrability” in debates about the modularity of cognition (McCauley & Henrich 2006).

Segall et al. manipulated the length of the two lines in the Mueller-Lyer illusion (Figure 1) and estimated the magnitude of the illusion for each participant—by determining the approximate point at which an individual perceives the two lines as being the same length. Figure 2 shows the results from 16 societies, including 14 small-scale societies. The vertical axis gives the ‘point of subjective equality’ (PSE), which measures the amount that segment ‘a’ must be longer than ‘b’ before the two segments are judged equal in length. PSE measures the strength of the illusion.

Figure 2: Mueller-Lyer Results for Segall et al.’s cross-cultural project. PSE is the percentage that segment ‘a’ must be longer than ‘b’ before individuals perceive them as equal.

The results show substantial differences among populations, with American undergraduates anchoring the extreme end of the distribution followed by the South African European sample, from Johannesburg. On average, the undergraduates required that segment ‘a’ be about a fifth

longer than 'b' before the two segments were perceived as equal. At the other end, the San foragers of the Kalahari were unaffected by the so-called "illusion" (it's not an illusion for them). While the San's PSE value cannot be distinguished from zero, the American undergraduates' PSE value is significantly different from all the other societies studied.

As discussed by Segall et. al., these findings suggest that visual exposure during ontogeny to factors such as the "carpentered corners" of modern environments may favor certain optical calibrations and visual habits that create and perpetuate the illusion. That is, the visual system ontogenetically adapts to the presence of recurrent features in the local visual environment. Since elements such as carpentered corners are products of particular cultural evolutionary trajectories, and were not part of most environments for most of human history, the Mueller-Lyer illusion is a kind of culturally-evolved byproduct (Henrich 2008).

These findings highlight three important considerations. First, this work suggests that even a process as apparently basic as visual perception can show substantial variation across populations. If visual perception can vary, what kind of psychological processes can we be sure will not vary? It's not merely that the strength of the illusory effect varies across populations – the effect cannot be detected in two populations. Second, both American undergraduates and children are at the extreme end of the distribution, showing significant differences from all other populations studied, whereas many of the other populations cannot be distinguished from one another. Since children already show large population-level differences, it is not obvious that developmental work can substitute for research across diverse human populations. Finally, this provides an example of how population-level variation can be useful for illuminating the nature of a psychological process, which would not be as evident in the absence of comparative work.

## 2.2 Economic Decision Making

By the mid-1990s researchers were arguing that a set of robust experimental findings from behavioral economics were evidence for set of evolved universal motivations (Fehr & Gächter 1998, Hoffman et al. 1998). Foremost among these experiments, the Ultimatum Game, provides a pair of anonymous subjects with a sum of real money for a one-shot interaction. One of the pair—the proposer—can offer a portion of this sum to a second subject, the responder. Responders must decide whether to accept or reject the offer. If a responder accepts, she gets the amount of the offer and the proposer takes the remainder; if she rejects both players get zero. If subjects are motivated purely by self-interest, responders should always accept any positive offer; knowing this, a self-interested proposer should offer the smallest non-zero amount. Among subjects from industrialized populations—mostly undergraduates from the U.S., Europe, and Asia—proposers typically offer an amount between 40% and 50% of the total, with a modal offer of usually 50% (Camerer 2003). Offers below about 30% are often rejected.

With this seemingly robust empirical finding in their sights, Nowak, Page and Sigmund (2000) constructed an evolutionary analysis of the Ultimatum Game. When they modeled the Ultimatum Game exactly as played, they did not get results matching the undergraduate findings. However, if they added reputational information, such that players could know what their partners did with others on previous rounds of play, the analysis predicted offers and rejections in the range of typical undergraduate responses. They concluded that the Ultimatum Game reveals humans' species-specific evolved capacity for fair and punishing behavior in situations with substantial reputation influence. But, since the Ultimatum Game is typically done one-shot without reputational information, they argued that people make fair offers and reject unfair offers because their motivations evolved in a world where such interactions were not fitness relevant—thus, we are not evolved to fully incorporate the possibility of non-reputational action in our decision-making, at least in such artificial experimental contexts.

Recent comparative work has dramatically altered this initial picture. Two unified projects (which we call Phase 1 and Phase 2) have deployed the Ultimatum Game and other related experimental tools across thousands of subjects randomly sampled from 23 small-scale human societies, including foragers, horticulturalists, pastoralists, and subsistence farmers, drawn from Africa, Amazonia, Oceania, Siberia and New Guinea (Henrich et al. 2005, Henrich et al. 2006). Three different experimental measures show that the people in industrialized societies consistently occupy the extreme end of the human distribution. Notably, small-scale societies with only face-to-face interaction behaved in a manner reminiscent of Nowak et. al.'s analysis before they added the reputational information. That is, these populations made low offers and did not reject.

To concisely present these diverse empirical findings, we show results only from the Ultimatum and Dictator Games in Phase II. The Dictator Game is the same as the Ultimatum Game except that the second player cannot reject the offer. If subjects are motivated purely by self-interest, they would offer zero in the Dictator Game. Thus, Dictator Game offers yield a measure of "fairness" (equal divisions) among two anonymous people. By contrast, Ultimatum Game offers yield a measure of fairness combined with an assessment of the likelihood of rejection (punishment). Rejections of offers in the Ultimatum Game provide a measure of people's willingness to punish unfairness.

Using aggregate measures, Figure 3 shows that the behavior of the U.S. adult (non-student) sample occupies the extreme end of the distribution in each case. For Dictator Game offers, Figure 3A shows that the U.S. sample has the highest mean offer followed by the Sanquianga from Colombia, who are renowned for their prosociality (Kraul 2008). The U.S. offers are nearly double that of the Hadza, foragers from Tanzania, and the Tsimane, forager-horticulturalists from the Bolivian Amazon. For Ultimatum Game offers, the U.S. has the second highest mean

offer behind the Sursurunga, from Papua New Guinea. For the punishment side in the Ultimatum Game, Figure 3C shows the income maximizing offers (IMO) for each population, which is a measure of the population's willingness to punish inequitable offers. IMO is the offer that an income-maximizing proposer would make if he knew the probability of rejection for each of the possible offer amounts. The U.S. sample is tied with the Sursurunga. These two groups have an IMO five times higher than 70% of the other societies. While none of these measures indicates that people from industrialized societies are entirely unique vis-à-vis other populations, they do show that people from industrialized societies consistently occupy the extreme end of the human distribution

Figure 3. Behavioral measures of fairness and punishment from the Dictator and Ultimatum Game for 15 societies (Phase II). Figure 3A and 3B show mean offers for each society in the Dictator and Ultimatum Games, respectively. Figure 3C gives the income-maximizing offer (IMO) for each society.

Analyses of these data show that a population's degree of market integration and its participation in a world religion both independently predict higher offers, and account for much of the variation between populations. Community size positively predicts greater punishment (Henrich et al. n.d.). The authors suggest that norms and institutions for exchange in ephemeral interactions culturally coevolved with markets and expanding larger-scale sedentary populations. In some cases, at least in their most efficient forms, neither markets nor large population were feasible before such norms and institutions emerged. That is, it may be that what behavioral economists have been measuring in such games is a specific set of social norms, evolved for dealing with money and strangers, that have emerged since the origins of agriculture and the rise of complex societies.

Suppose that Nowak and his coauthors were Tsimane, and that the numerous empirical findings they had on hand were all from Tsimane villages. If this were the case, presumably these researchers would have simulated the Ultimatum Game and found that there was *no need to add* reputation to their model. This unadorned evolutionary solution would have worked fine until they realized that the Tsimane are not representative of humanity. According to the above data, the Tsimane are about as representative of the species as are Americans, but at the opposite end of the spectrum. Would we not be concerned about the foundations of our theories of economic decision making if our database consisted entirely of Tsimane subjects?

### 2.3 Folkbiological Reasoning

Recent work in small-scale societies suggests that *some* of the central conclusions regarding the development and operation of human folkbiological categorizing, reasoning, and induction are limited to urban subpopulations of non-experts in industrialized societies. While much more work needs to be done, it appears that typical subjects (children of WEIRD parents) develop their folkbiological reasoning in a culturally and experientially impoverished environment, by contrast to those of small-scale societies (and of our evolutionary past), distorting the species-typical pattern of cognitive development, as well as adult patterns of reasoning for WEIRD people.

Cognitive scientists using children drawn from U.S. urban centers, often surrounding universities, have constructed a developmental theory in which folkbiological reasoning emerges from folkpsychological reasoning. Before age 7 urban children reason about biological phenomena by analogy to, and by extension from, humans. Between ages 7 and 10 urban children undergo a conceptual shift to the adult pattern of viewing humans as one animal among many. These conclusions are underpinned by three robust findings from urban children: (1) inferential projections of properties from humans are stronger than projections from other living kinds, (2) inferences are asymmetric, with inferences from human properties to mammals emerging as stronger than inference from mammals to humans, and (3) children's inferences

violate their own similarity judgments by, for example, providing stronger inference from humans to bugs than from bugs to bees (Carey 1985;1995).

However, when the folkbiological reasoning of rural Native American communities in Wisconsin and Yukatek Maya was investigated (Ross et al. 2003, Waxman & Medin 2007), none of these three empirical patterns emerged. Among the Yukatek Maya, the human category appears to be incorporated into folkbiological induction relatively late. The results indicate that some background knowledge of the relevant species is crucial for the application and induction across a hierarchical taxonomy (Atran et al. 2001). In rural environments both exposure to, and interest in, the natural world is commonplace, unavoidable, and an inevitable part of the enculturation process. This suggests that the anthropocentric patterns seen in U.S. urban children result from insufficient cultural input and a lack of exposure to the natural world. The only real animal that most urban children know much about is *Homo sapiens*, so it is not surprising that this species dominates their inferential patterns. Since such urban environments are highly “unnatural” from the perspective of human evolutionary history, any conclusions drawn from subjects reared in such informationally depauperate environments must remain rather tentative. Indeed, studying the cognitive development of folkbiology in urban children would seem the equivalent of studying “normal” physical growth in malnourished children.

This deficiency of input likely underpins the fact that the basic level biological categories for WEIRD adults are life-form categories (e.g., bird, fish, and mammal) and these are also the first categories learned by children: e.g., if you say “what’s that” (pointing at a maple tree), the common answer is “tree”. However, in all small-scale societies studied, the generic species (e.g., trout, fox, and maple) are the basic level category and the first learned by children (Atran 1993, Berlin 1992).

Impoverished interactions with the natural world may also distort assessments of the typicality of natural kinds in categorization. The standard conclusion from American undergraduate samples has been that goodness of example, or typicality, is driven by similarity relations. A robin is a typical bird because this species shares many of the perceptual features that are commonly found in the category BIRD. In the absence of close familiarity with natural kinds, this is the default strategy of American undergraduates, and psychology has assumed it is the universal pattern. However in samples which interact with the natural world regularly, such as professional taxonomists or Itza Maya villagers, typicality is based not on similarity, but on knowledge of cultural ideals, reflecting the symbolic or material significance of the species in that culture. For the Itza, the wild turkey is a typical bird, because of its rich cultural significance, even though it is in no way most similar to other birds. The same pattern holds for similarity effects in inductive reasoning—WEIRD people make strong inferences from computations of similarity, whereas populations with greater familiarity with the natural world

make strong inferences from folkbiological knowledge that takes into account ecological context and relationships among species (Atran et al. 2005). In general, research suggests that *what* people think about can affect *how* they think (Bang et al. 2007). To the extent that there is population-level variability in the content of folkbiological beliefs, such variability affects cognitive processing in this domain.

Above we emphasized differences in folkbiological cognition uncovered by comparative research. This same work has also uncovered reliably developing aspects of human folkbiological cognition that do not vary, such as categorizing plants and animals in a hierarchical taxonomy, or that the generic species level has the strongest inductive potential, despite the fact that this level is not always the basic level across cultures. Our goal in emphasizing the differences here is to show (1) how peculiar industrialized (urban in this case) samples are given the unprecedented environment they grow up in, and (2) how difficult it is to conclude *a priori* what aspects will be reliably developing and robust across diverse slices of humanity if research is largely conducted with WEIRD samples.

## 2.4 Spatial Cognition

Human societies vary in their linguistic tools for, and cultural practices associated with, representing and communicating (1) directions in physical space, (2) the color spectrum, and (3) integer amounts. There is some evidence that each of these differences in cultural content may influence some aspects of non-linguistic cognitive processes (D'Andrade 1995, Gordon 2005, Kay 2005, Levinson 2003). Here we focus on spatial cognition, for which the evidence is most provocative. As above, it appears that industrialized societies are at the extreme end of the continuum in spatial cognition. Human populations show differences in how they think about spatial orientation and deal with directions, and these differences may be influenced by linguistically-based spatial reference systems.

Speakers of English and other Indo-European languages favor the use of an egocentric (relative) system to represent the location of objects relative to the self (e.g., “the man is on the right side of the flagpole”). In contrast, many if not most, languages, favor an allocentric frame which comes in two flavors. Some allocentric languages such as Guugu Yimithirr (an Australian language) and Tzeltal (a Mayan language) favor a geocentric system in which absolute reference is based on cardinal directions (“the man is west of the house”). The other allocentric frame is an object-centered (intrinsic) approach that locates objects in space, relative to some coordinate system anchored to the object (“the man is behind the house”). When languages possess systems for encoding all of these spatial reference frames, they often privilege one at the expense of the others. However, the fact that some languages lack one or more of the reference systems suggests that the accretion of all three systems into most contemporary languages may be a product of long-term cumulative cultural evolution.

In data on spatial reference systems from 20 languages drawn from diverse societies—including foragers, horticulturalists, agriculturalists, and industrialized populations—only three languages relied on egocentric frames as their single preferred system of reference. All three were from industrialized populations: Japanese, English and Dutch (Majid et al. 2004).

The presence of, or emphasis on, different reference systems may influence non-linguistic spatial reasoning (Levinson 2003). In one study, Dutch and Tzeltal speakers were seated at a table and shown an arrow pointing either to the right (north) or the left (south). They were then rotated 180 degrees to a second table where they saw two arrows: one pointing to the left (north) and the other one pointing to the right (south). Participants were asked which arrow on the second table was like the one they saw before. Consistent with the spatial-marking system of their languages, Dutch speakers chose the relative solution, whereas the Tzeltal speakers chose the absolute solution. Several other comparative experiments testing spatial memory and reasoning are consistent with this pattern, although lively debates about interpretation persist (Levinson et al. 2002, Li & Gleitman 2002).

Extending the above exploration, Haun and colleagues (2006, 2006) examined performance on a spatial reasoning task similar to the one described above using children and adults from different societies and great apes. In the first step, Dutch-speaking adults and eight-year olds (speakers of an egocentric language) showed the typical egocentric bias, whereas Hai//om-speaking adults and eight-year olds (a Namibian foraging population who speak an allocentric language) showed a typical allocentric bias. In the second step, four-year old German-speaking children, gorillas, orangutans, chimpanzees, and bonobos were tested on a simplified version of the same task. All showed a marked preference for allocentric reasoning. These results suggest that children share with other great apes an innate preference for allocentric spatial reasoning, but that this bias can be overridden by input from language and cultural routines.

If one were to work on spatial cognition exclusively with WEIRD subjects (say, using subjects from Japan, the U.S. and Europe) one might conclude that children start off with an allocentric bias but naturally shift to an egocentric bias with maturation. The problem with this conclusion is that it would not apply to many human populations, and may be the product of particular cultural environments. The next contrast highlights some additional evidence suggesting that WEIRD people may be unusual in their egocentric bias.

We have discussed several lines of data suggesting, not only population-level variation, but that WEIRD people are unusual. There are also numerous studies that have found differences between much smaller numbers of samples. In these studies it is impossible to discern whether the results of the small-scale societies or those of the industrialized societies are more unusual. For example, one study found that both samples from two different industrialized populations were risk-averse decision makers when facing monetary gambles involving gains (Henrich &

McElreath 2002) while both samples of small-scale societies were risk-prone. It might be that such risk-aversion is a local phenomenon. Similarly, extensive inter-temporal choice experiments using a panel method of data collection indicates that the Tsimane, an Amazonian population of forager-horticulturalists, discount the future 10 times more steeply than WEIRD people (Godoy et al. 2004).

## 2.5 Similarities Between Industrialized and Small-Scale Societies

Some larger-scale comparative projects show universal patterns in human psychology. Here we list some noteworthy examples:

- 1) Illusions: We discussed the Mueller-Lyer illusion above. However, there are illusions, such as the Perspective Drawing Illusion, for which perception does not vary much in the populations studied (Segall et al. 1966).
- 2) Perceiving color: While the number of basic color terms systematically varies across human languages (Regier et al. 2005), the ability to perceive different colors does emerge in small-scale societies (Rivers 1901),<sup>2</sup> although terms and categories do influence color perception at the margins (Kay & Regier 2006).
- 3) Emotional expression: In studying facial display of emotions, Ekman and colleagues have shown much evidence for universality in recognition of the “basic” facial expressions of emotions, although this work has included only a small—yet convincing—sampling of small-scale societies (Ekman 1999a;1999b). There is also evidence for the universality of pride displays (Tracy & Matsumoto 2008, Tracy & Robins 2008). This main effect for emotional recognition across population (58% of variance) is qualified by a smaller effect for cultural specificity of emotional expressions (9% of variance: Elfenbein & Ambady 2002).
- 4) Theory of mind: Comparative work in China, the U.S., Canada, Peru, India, Samoa and Thailand suggests that theory of mind emerges in all populations studied (Callaghan et al. 2004, Liu et al. 2008), although the age at which subjects can pass the explicit version of the false belief task varies from 4 to at least 9 (Boesch 2007), with industrialized populations at the extreme low end.
- 5) Analog numeracy: There is growing consensus in the literature on numerical thinking that quantity estimation relies on a primitive “analog” number sense that is sensitive to quantity but limited in accuracy. This cognitive ability appears to be independent of counting practices, was shown to operate in similar ways among two Amazonian societies with very limited counting systems (Gordon 2005, Pica et al. 2004), as well as in infants and primates (e.g., Dehaene 1997).

6) Social relationships: Research on the cognitive processes underlying social relationships reveals similar patterns across distinct populations. Fiske (1993) studied people's tendency to confuse one person with another (e.g., intending to phone your son Bob but accidentally calling your son Fred). Chinese, Korean, Bengali and Vai (Liberia and Sierra Leone) immigrants tended to confuse people in the same category of social relationship. Interestingly, the social categories in which the most confusion occurred varied across populations.

There are also numerous studies in which dyadic comparisons have been made between a single small-scale society and a western population (or a pattern of western results), in which cross-cultural similarities have been found. Examples are numerous but include the development of an understanding of death (Barrett & Behne 2005), shame (Fessler 2004)<sup>3</sup> and cheater detection (Sugiyama et al. 2002). Finding evidence for similarities across two such disparate populations is an important step towards providing evidence for universality (Norenzayan and Heine 2005); however, the case would be considerably stronger if it was found across a larger number of diverse populations.<sup>4</sup>

## 2.6 Summary for Contrast 1

Although there are several domains in which the data from small-scale societies appear similar to that from industrialized societies, comparative projects involving visual illusions, social motivations (fairness), folkbiological cognition, and spatial cognition all show industrialized populations as outliers. For these latter domains, it is problematic to assume that the findings from industrialized populations are generalizable to humans more broadly.

## 3 Contrast 2: Western<sup>5</sup> vs. Non-Western Societies

For our second contrast, we review evidence comparing Western to non-Western populations. Here we examine four of the most studied domains, including decision-making and punishment, independent vs. interdependent self-concepts (and associated motivations), analytic vs. holistic reasoning, and moral reasoning. We also briefly return to spatial cognition.

### 3.1 Anti-social punishment and cooperation with anonymous others

In the previous contrast we reviewed decision-making experiments showing that industrialized populations occupy the extreme end of the behavioral distribution vis-à-vis a broad swath of smaller-scale societies. Here we show that even among industrialized populations, Westerners are again clumped at the extreme end of the behavioral distribution. Notably, the behaviors measured in the experiments discussed below are strongly correlated with the strength of formal institutions, norms of civic cooperation, and GDP per capita.

In 2002 Fehr and Gächter published their classic paper, "Altruistic Punishment in Humans," in *Nature*, based on public goods games with and without punishment conducted with undergraduates at the University of Zurich. The paper demonstrated that adding the possibility of punishment to a cooperative dilemma dramatically altered the outcome from a gradual slide towards little cooperation (and rampant free-riding) to a steady increase towards stable cooperation. Enough subjects were willing to punish non-cooperators at a cost to themselves to shift the balance from free-riding to cooperation.

To examine the generalizability of these results, which many took to be a feature of our species, Herrmann, Thoni and Gächter (2008) conducted systematic comparable experiments among undergraduates from a diverse swath of industrialized nations. In these public good games, subjects played with the same four partners for 10 rounds and could contribute during each round to a group project. All contributions to the group project were multiplied by 1.6 and distributed equally among all partners. Players could also pay to punish other players by taking money away from them.

In about half of these samples, Gächter's team found something not observed beyond a trivial degree in Western subjects (see Figure 4): many subjects engaged in *anti-social* punishment; that is, they paid to reduce the earning of "overly" cooperative individuals (those who contributed more than the punisher). The effect of this behavior on levels of cooperation was dramatic, completely compensating for the cooperation-inducing effects of punishment in the Zurich experiment. Possibilities for altruistic punishment do not generate high levels of cooperation in these populations. Meanwhile, participants from a number of Western countries, such as the U.S., U.K, and Australia, behaved like the original Zurich students. Thus, it appears that the Zurich sample works well for generalizing to the patterns of other Western samples (as well as the Chinese sample), but such findings cannot be readily extended beyond this.

Fig. 4. Mean punishment expenditures from each sample for a given deviation from the punisher's contribution to the public good. The deviations of the punished subject's contribution from the punisher's contribution are grouped into five intervals, where [-20,-11] indicates that the punished subjects contributed between 11 and 20 less than the punishing subject; [0] indicates that the punished subject contributed exactly the same amount as the punishing subject and [1,10] ([11,20]) indicates that the punished subject contributed between 1 and 10 (11 and 20) more than the punishing subject. Adapted from Herrmann et. al. (2008).

### 3.2 Independent and Interdependent Self-Concepts

Much research has explored the nature of people's self-concepts. Self-concepts are important as they organize the information that people have about themselves, direct attention to information that is perceived to be relevant, shape motivations, influence how people appraise situations that influence their emotional experiences, and guide their choices of relationship partners. Markus and Kitayama (1991) posited that self-concepts can take on a continuum of forms stretching between two poles, termed independent and interdependent self-views. Do people conceive of themselves primarily as self-contained individuals, understanding themselves as autonomous agents that consist largely of component parts, such as their

attitudes, personality traits, and abilities? Or do they conceive of themselves as interpersonal beings intertwined with one another in social webs, with incumbent role-based obligations towards others within those networks? The extent to which people perceive themselves in ways similar to these independent or interdependent poles has significant consequences for a variety of emotions, cognitions, and motivations.

Much research has underscored how Westerners have more independent views of self than non-Westerners. For example, research using the Twenty Statements Test (Kuhn & McPartland 1954) reveals that people from Western populations (e.g., Australians, Americans, Canadians, Swedes) are far more likely to understand their selves in terms of internal psychological characteristics, such as their personality traits and attitudes, and are less likely to understand them in terms of roles and relationships, than are people from non-Western populations, such as Native Americans, Cook Islanders, Maasai, Samburu (both African pastoralists), Malaysians, and East Asians (for a review see Heine 2008). Studies using other measures (Hofstede 1980, Morling & Lamoreaux 2008, Oyserman et al. 2002) provide convergent evidence that Westerners tend to have more independent, and less interdependent, self-concepts than those of other populations. These data converge with much ethnographic observation, in particular Geertz's (1974: 16) claim that the Western self is, "a rather peculiar idea within the context of the world cultures."

There are numerous psychological patterns associated with self-concepts. For example, people with independent self-concepts are more likely to demonstrate (1) positively biased views of themselves; (2) tendencies to base long-term relationships on feelings of romantic love; (3) a heightened valuation of personal choice; and (4) an increased motivation to "stand out" rather than to "fit in." Each of these represents a significant research enterprise, and we discuss them in turn.

### 3.2.1 Positive Self-Views

The most widely endorsed assumption regarding the self is that people are motivated to view themselves positively. Brown (1986) famously declared this motivation to maintain high self-esteem an "urge so deeply human, we can hardly imagine its absence" (p. 534). The strength of this motivation has been perhaps most clearly documented by assessing the ways that people go about exaggerating their self-views by engaging in self-serving biases, in which people view themselves more positively than objective benchmarks would justify. For example, in one study, ninety-four percent of American professors rated themselves as better-than-average (Cross 1977). However, meta-analyses reveals that these self-serving biases tend to be more pronounced in Western populations than in non-Western ones (Heine & Hamamura 2007, Mezulis et al. 2004)—for example, Mexicans (Tropp & Wright 2003), Native Americans (Fryberg & Markus 2003), Chileans (Heine & Raineri 2009), and Fijians (Rennie & Dunne 1994) score

much lower on various measures of positive self-views than do Westerners (although there are some exceptions to this general pattern: Harrington & Liu 2002). Indeed, in some cultural contexts, most notably East Asian ones, evidence for self-serving biases tends to be null, or in some cases, show significant reversals, with East Asians demonstrating self-effacing biases (Heine & Hamamura 2007). At best, the sharp self-enhancing biases of Westerners are less pronounced in much of the rest of world, though self-enhancement has long been discussed as if it were a fundamental aspect of human psychology (e.g., Rogers 1951, Tesser 1988).

### 3.2.2 *Romantic Love as a Basis of Marriage*

While feelings of romantic love appear to be universally experienced (see meta-analysis of ethnographies by Jankowiak & Fischer 1992), romantic love as the basis of a marriage is not universally recognized. Marriages are less likely to be based on romantic love (i.e., they are arranged by other family members) in “collectivistic” societies where extended family ties are stronger (see meta-analysis by Lee & Stone 1980); in the absence of family and social pressures, romantic love apparently becomes more important to hold the relationship together. In one international survey of students from India, Pakistan, Thailand, the U.S., England, Japan, Philippines, Mexico, Brazil, Hong Kong, Australia, the vast majority of university students from Western countries (as well as Hong Kong) said that they would *not* marry someone unless they loved them. In contrast, students from most of the non-Western populations that were studied were more likely to entertain marriage preceding love (Levine et al. 1995). Ironically, the greater emphasis on romantic love in marriages among Westerners is paralleled by a higher divorce rate (United Nations Statistics Division, 2004). Marriages which are largely based on romance among Westerners appear to exist in more conditional and tenuous terms than they do in populations where the marriages are not founded on romantic love. Perhaps as a consequence, much research on relationships has attended to the loss of love and its relation to the dissolution of long-term relationships (e.g., Gottman 1993, Rusbult 1983).

### 3.2.3 *Personal Choice*

Psychology has long been fascinated with how people assert agency by making choices (Bandura 1982, Kahneman & Tversky 2000, Schwartz 2004), and has explored the efforts that people go through to ensure that their actions *feel* freely chosen and that their choices are sensible. However, there is considerable variation across populations in the extent by which people value choice and the range of behaviors over which they feel that they are making choices. For example, one study found that European-American children preferred working on a task, worked on it longer, and performed better on it, if they had made some superficial choices regarding the task than if others made the same choices for them. In contrast, Asian-American children were equally motivated by the task if a trusted other made the same choices for them (Iyengar & Lepper 1999). Another study found that Indians were slower at making choices, and

were less likely to make choices consistent with their personal preferences, than were Americans (Savani et al. 2008). Surveys conducted at bank branches in countries in Argentina, Brazil, Mexico, Philippines, Singapore, Taiwan, and the United States found that Americans were more likely to perceive having more choice at their jobs than those from the other countries (Iyengar & DeVoe 2003). A large-scale value survey administered in over 40 countries from around the world found, in general, that feelings of free choice in one's life were considerably higher in Western nations (e.g., Finland, the US, and Northern Ireland) than in various non-Western nations (e.g., Turkey, Japan, and Belarus: Inglehart et al. 1998). This research reveals that perceptions of choice are experienced less often, and are a lesser concern, among those from non-Western populations.

### 3.2.4 Motivations to Conform

Many studies have explored whether conformity motivations are similar across populations by employing a standard experimental procedure (Asch 1951, Bond 1996). In these studies, which were initially conducted with Americans, participants first heard a number of confederates making an incorrect visual judgment, and then were given the opportunity to state their own judgment. A majority of American participants were found to go along with the majority's incorrect judgment at least once. This research sparked much interest, and a meta-analysis of studies performed in 17 societies (Bond & Smith 1996), including subjects from Oceania, the Middle East, South America, Africa, South America, East Asia, Europe, and the U.S., found that motivations for conformity are weaker in Western societies than elsewhere. Other research provides convergent findings to the notion that motivations for conformity are weaker in Western contexts. For example, Kim and Markus (1999) found that Koreans preferred more common objects while Americans preferred more unusual objects.

## 3.3 Analytic vs. Holistic Reasoning

Variation in favored modes of reasoning has been compared across several populations. Most of the research has contrasted Western (American, Canadian, Western European) with East Asian (Chinese, Japanese, Korean) populations with regard to their relative reliance on what is known as holistic vs. analytic reasoning (Nisbett 2003, Peng & Nisbett 1999). However, growing evidence from other non-Western populations point to a divide between Western nations and most everyone else, including groups as diverse as Arab, Malaysian, and Russians (see Norenzayan et al. 2007 for review), as well as subsistence farmers and sedentary foragers (Norenzayan et al. n.d., Witkin & Berry 1975), rather than an East-West divide. Holistic thought involves an orientation to the context or field as a whole, including attention to relationships between a focal object and the field, and a preference for explaining and predicting events on the basis of such relationships. Analytic thought involves a detachment of objects from contexts, a tendency to focus on objects' attributes, and a preference for using categorical rules

to explain and predict behavior. This distinction between habits of thought rests on a theoretical partition between two reasoning systems. One system is associative, and its computations reflect similarity and contiguity (i.e., whether two stimuli share perceptual resemblances and co-occur in time); the other system relies on abstract, symbolic representational systems, and its computations reflect a rule-based structure (e.g., Neisser 1963, Sloman 1996).

Although both cognitive systems are available in all normal adults, different environments, experiences, and cultural routines may encourage reliance on one system at the expense of another, giving rise to population-level differences in the use of these different cognitive strategies to solve identical problems. There is growing evidence that a key factor influencing the prominence of analytic vs. holistic cognition is the different self-construals prevalent across populations. First, independent self-construal primes facilitate analytic processing, whereas interdependent primes facilitate holistic processing (Oyserman & Lee 2008). Second, geographic regions with greater prevalence of interdependent self-construals show more holistic processing, as can be seen in comparisons of Northern and Southern Italians, Hokkaido and mainland Japanese, and Western and Eastern Europeans (Varnum et al. 2008).

Furthermore, the analytic approach is culturally more valued in Western contexts, whereas the holistic approach is more valued in East Asian contexts, leading to normative judgments about cognitive strategies that differ across the respective populations (e.g., Buchtel & Norenzayan, in press). Below we highlight some findings from this research showing that, compared to diverse populations of non-westerners, **Westerners (1) attend more to objects than fields;** (2) explain behavior in more decontextualized terms; (3) rely more on rules over similarity relations to classify objects; (for further discussion of the cross-cultural evidence Nisbett 2003, Norenzayan et al. 2007).

- 1) Using evidence derived from the Rod & Frame Test and Embedded Figures Test, Witkin and Berry (1975) summarize a wide range of evidence from migratory and sedentary foraging populations (Arctic, Australia and Africa), sedentary agriculturalists, and industrialized Westerners. **Only Westerners and migratory foragers consistently emerged at the field independent end of the spectrum.** Recent work among East Asians (Ji et al. 2004) in industrialized societies using the Rod & Frame Test, the Framed Line Test (Kitayama 2003), and the Embedded Figures Test again shows Westerners at the field independent end of the spectrum, compared to field dependent East Asians, Malays and Russians (Grossmann 2008, Kuhnen et al. 2001). Similarly, Norenzayan et al. (2007) found that Canadians showed less field-dependent processing than Chinese, who in turn were less field-dependent than Arabs (also see Zebian & Denny 2001).

- 2) East Asians' recall for objects is worse than Americans if the background has been switched (Masuda & Nisbett 2001), indicating that they are attending to the field more. This difference in attention has also been found in saccadic eye-movements as measured with eye-trackers. Americans gaze at focal objects longer than East Asians, who in turn gaze at the background more than Americans (Chua et al. 2005). **Furthermore, when performing these identical tasks East Asians and Westerners show differential brain activation**, corresponding to brain regions associated with attentional control and object-processing (Gutchess et al. 2006, Hedden et al. 2008).
- 3) Several classic studies, initially conducted with Western participants, found that people tend to make strong attributions about a person's disposition, even when there are compelling situational constraints (Jones & Harris 1967, Ross et al. 1977). This tendency to ignore situational information in favor of personality information is so commonly observed—among typical subjects—that it was dubbed the “fundamental attribution error” (Ross et al. 1977). However, consistent with much ethnography in non-Western cultures (e.g., Geertz 1975), comparative experimental work demonstrates differences that, while Americans attend to dispositions at the expense of situations (Gilbert & Malone 1995), East Asians are more likely than Americans to infer that behaviors are strongly controlled by the situation (Miyamoto & Kitayama 2002, Morris & Peng 1994, Norenzayan, Choi et al. 2002, Van Boven et al. 1999), particularly when situational information is made salient (Choi & Nisbett 1998).<sup>6</sup> Grossmann et. al. provide parallel findings with Russians (Grossmann 2008). Likewise, in an investigation of people's lay beliefs about personality across eight populations, Church et al. (2006) found that people from Western populations (i.e., American and Euro-Australian) strongly endorsed the notions that traits remain stable over time and predict behavior over many situations, while those from non-Western populations (i.e., Asian-Australian, Chinese-Malaysian, Filipino, Japanese, Mexican, and Malay) more strongly endorsed contextual beliefs about personality, such as ideas that traits do not describe a person as well as roles or duties, and that trait-related behavior changes from situation to situation. These patterns are consistent with earlier work on attributions comparing Euro-Americans with Hindu Indians (see Shweder and Bourne (1982) and Miller (1984)). Thus, although dispositional inferences can be found outside the West, the fundamental attribution error seems less fundamental elsewhere (Choi et al. 1999).
- 4) Westerners are also more likely to rely on rules over similarity relations in reasoning and categorization. Chinese subjects were found to be more likely to group together objects which shared a functional (e.g., pencil-notebook) or contextual (e.g., sky-sunshine) relationship while Americans were more likely to group objects together if they belonged to a category defined by a simple rule (e.g., notebook-magazine, (Ji et al.

2004). Similarly, work with Russian students (Grossman, 2008), and Russian peasants (Luria, 1976), showed strong tendencies for participants to group objects according to their practical functions. This appears widespread, as Norenzayan et. al. (n.d.) examined classification among the Mapuche and Sangu subsistence farmers in Chile and Tanzania, respectively, and found that their classification resembled the Chinese pattern, although it was exaggerated towards holistic reasoning.

- 5) In a similar vein, research with East Asians found they were more likely to group objects if they shared a strong family resemblance structure, whereas Americans were more likely to group the same objects if they could be assigned to that group on the basis of a deterministic rule (Norenzayan, Smith et al. 2002). When those results are compared to Uskul et. al.'s (2008) findings from herders, fishermen, and farmers living on the northeast coast of Turkey, it is evident that European Americans are again at the extreme (Figure 5).

**Fig. 5. Relative dominance of rule-based versus family resemblance-based judgments of categories for the same cognitive task.** European-American, Asian-American, and East Asian university students were tested by Norenzayan et al, 2002; the herders, fishermen, and farmers of Turkey's Black Sea coast were tested by Uskul et al, 2008. Positive scores indicate a relative bias towards rule-based judgments, whereas negative scores indicate a relative bias towards a family-resemblance based judgments. It can be seen that European American students show the most pronounced bias towards rule-based judgments, and are outliers in terms of absolute deviation from zero. Adapted from Norenzayan et al, 2002, and Uskul et al 2008.

In summary, although these cognitive systems are available to all normal adults, a large body of evidence shows that the habitual use of what are considered “basic” cognitive processes, including those involved in attention, perception, categorization, deductive reasoning, and social inference, vary systematically across populations in predictable ways, highlighting the

difference between the West and the rest. Several biases and patterns are not merely differences in strength or tendency, but show reversals of Western patterns. We emphasize that Westerners are not unique in their cognitive styles (Uskul et al. 2008, Witkin & Berry 1975), but they do occupy the extreme end of the distribution.

### 3.4 Moral Reasoning

A central concern in the developmental literature has been the way people acquire the cognitive foundations of moral reasoning. The most influential approach to the development of moral reasoning has been Kohlberg's (1971, 1976, 1981) framework, in which people's abilities to reason morally are seen to hinge on cognitive abilities that develop over maturation. Kohlberg proposed that people progressed through the same three levels: 1) children start out at a pre-conventional level, viewing right and wrong as based on the physical or hedonistic consequences of actions; 2) then they progress to a conventional level, where moral behavior is perceived to be that which maintains the social order of their group; and finally 3) some progress further to a post-conventional level, evaluating right and wrong on the basis of abstract ethical principles regarding justice and individual rights—the moral code inherent in the U.S. Constitution.

While all of Kohlberg's levels are commonly found in WEIRD populations, much subsequent research has revealed scant evidence for post-conventional moral reasoning in other populations. One meta-analysis carried out with data from 27 countries found consistent evidence for post-conventional moral reasoning in all the Western urbanized samples, yet found no evidence for this type of reasoning in small-scale societies (Snarey 1985). Furthermore, it is not just that formal education is necessary to achieve Kohlberg's post-conventional level. Some highly educated non-Western populations do not show this post-conventional reasoning. At Kuwait University, for example, faculty members score lower on Kohlberg's schemes than the typical norms for Western adults, and the elder faculty there scored no higher than the younger ones, contrary to Western patterns (Al-Shehab 2002, Miller et al. 1990).

Research in moral psychology also indicates that non-Western adults and Western religious conservatives rely on a wider range of moral principles than a morality of justice (Baek 2002, Haidt & Graham 2007, Haidt et al. 1993, e.g., Miller & Bersoff 1992). Shweder, Much, Mahapatra, and Park (1997) proposed that in addition to a dominant justice-based morality, which they termed an ethic of autonomy, there are two other ethics that are commonly found outside the West: an ethic of communion, in which morality derives from the fulfillment of interpersonal obligations, and an ethic of divinity in which moral decisions are based on the fit with a perceived natural order (for a further elaboration of moral foundations see Haidt & Graham 2007). In sum, the high-SES, secular Western populations that have been the primary

target of study thus far appear unusual in a global context, based on their peculiar reliance on a single foundation for moral reasoning (based on justice and individual rights).

### **Other Differences**

With reference to the spatial reasoning patterns discussed earlier, emerging evidence suggests that a geocentric bias may be much more widespread than previously thought—indeed, it may be the common pattern outside of the West (even among non-Western speakers of languages which make regular use of egocentric linguistic markers). Comparative research contrasting children and adults in Geneva with samples in Indonesia, Nepal, and rural and urban India have found the typical geocentric reasoning pattern in all of these populations except for the Geneva samples (Dasen et al. 2006). While many of these population-level differences are pronounced, more research is needed before we can assess whether the geocentric pattern is common across a broader swath of humanity.

There are many other psychological phenomena in which Western samples differ from non-Western ones; however, at present there insufficient data in these domain from diverse populations to assess where Western reside in the human spectrum. For example, compared with Westerners, non-Westerners may 1) view enemies as an important aspect of relationships (Adams 2005), 2) prefer lower to higher arousal positive affective states (Tsai 2007), 3) be less egocentric in their perspective-taking (Cohen et al. 2007, Wu & Keysar 2007), 4) have weaker motivations for consistency (Kanagawa et al. 2001, Suh 2002), 5) be less prone to social loafing (Earley 1993), (6) associate fewer benefits with a person's physical attractiveness (Anderson, Adams, & Plaut, 2008), and (7) have more pronounced avoidance motivations (Elliot et al. 2001, Lee et al. 2000).

### **3.5 Similarities Between Western and Non-Western Societies**

We expect that as more large-scale comparative studies of Western and non-Western populations are conducted, they will reveal substantial similarities in psychological processes. However, given the relative ease of conducting such studies (as compared to working in small-scale societies) there have been few comparative programs that have put universality claims to the test. Here we highlight four examples of larger-scale comparative projects that show broad and important similarities across populations.

- 1) Mate preferences: Buss (1989) compared people from 37 (largely industrialized) populations around the world and found some striking similarities in their mate preferences. In all 37 of the populations, males ranked the physical attractiveness of their mates to be more important than did females, and in 34 of the 37 populations, females ranked the ambition and industriousness of their mates as more important than did males (but for other interpretations see Eagly & Wood 1999).<sup>7</sup> Likewise, Kenrick and

Keefe (1992a, 1992b) provide evidence of robust differences in age preferences of mates across cultures. Comparative research examining men's preferred waist to hip ratios in potential mates finds that men in both industrialized and developing large-scale populations prefer a waist to hip ratio of around 0.7 (Singh 2006, Singh & Luis 1994, 2003, Swami et al. 2007).<sup>8</sup>

- 2) Personality structure: recent efforts have taken personality instruments to university students in 51 different countries (McCrae et al. 2005). In most of these populations the same factor structure emerges that has previously been found with American samples, although the factor structure was less evident in a number of developing populations (e.g., Botswana, Ethiopia, Lebanon, Malaysia, Puerto Rico, Uganda). To the extent that unfamiliarity with Western measures can account for the anomalous factor structure in these populations this is good evidence that the Five Factor Model reflects the universal structure of personality (also see Allik & McCrae 2004, Yik et al. 2002).<sup>9</sup>
- 3) Punishment of free-riding: While in Hermann et. al.'s study (Figure 4) anti-social punishment varied dramatically, the willingness of players to punish low contributors (free-riders) was not different among populations, once age, sex, and other sociodemographic controls are included.

### 3.6 Summary of Contrast 2

While robust patterns have emerged among people from industrialized societies, Westerners emerge as unusual, frequent global outliers, on several key dimensions. The experiments reviewed are numerous, arise from different disciplines, use diverse methods, and are often part of systematically comparable data sets created by unified projects.

## 4 Contrast 3: Contemporary Americans<sup>10</sup> vs. the Rest of West

Above we considered evidence that WEIRD populations respond differently from non-Western populations. However, there is variation within the West, and thus, given the dominance of American research within psychology (May, 1997), it is important to assess the similarity of American data with that from Westerners more generally. Is it reasonable to generalize from Americans to the rest of the West? Americans are, of course, people too, so they will share many psychological characteristics with other *Homo sapiens*. At present, we could find no systematic research program to compare Americans to other Westerners, so the evidence presented is assembled from many sources

## 4.1 Individualism and Related Psychological Phenomena

Americans stand out relative to Westerners for phenomena that are associated with independent self-concepts and individualism. A number of analyses, using a diverse range of methods, reveal that Americans are, on average, the most individualistic people in the world (e.g., Hofstede 1980, Lipset 1996, Morling & Lamoreaux 2008, Oyserman et al. 2002). The observation that the U.S. is especially individualistic is not new, and dates at least as far back as Toqueville (1835). The unusually individualistic nature of Americans may be caused by, or reflect, an ideology that particularly stresses the importance of freedom and self-sufficiency, as well as various practices in education and child-rearing that may help to inculcate this sense of autonomy. American parents, for example, were the only ones in a survey of 100 societies who created a separate room for their baby to sleep (Burton & Whiting 1961, also see Lewis 1995), reflecting that from the time they are born, Americans are raised in an environment that emphasizes their independence (on unusual nature of American childrearing, see Lancy 2009, Rogoff 2003).

The extreme individualism of Americans is evident on many demographic and political measures. In *American Exceptionalism*, sociologist Seymour Lipset (1996) documents a long list of the ways that Americans are unique in the Western world. At the time of Lipset's surveys, compared with other Western industrialized societies, Americans were found to be the most patriotic, litigious, philanthropic, and populist (they have the most positions for elections and the most frequent elections, although they have among the lowest turnout rates). They were also among the most optimistic, and the least class-conscious. They were the most churchgoing in Protestantism, and the most fundamentalist in Christendom, and were more likely than others from Western industrialized countries to see the world in absolute moral terms. In contrast to other large Western industrialized societies, the US had the highest crime rate, the longest working hours, the highest divorce rate, the highest rate of volunteerism, the highest percentage of citizens that went on to post-secondary education, the highest productivity rate, the highest GDP, the highest poverty rate, the highest income inequality rate, and were in the least support of various governmental interventions. The U.S. is the only industrialized society that never had a viable socialist movement, and was the last country to get a national pension plan, unemployment insurance, accident insurance, and remains the only industrialized nation that does not have a general allowance for families or a national health insurance plan. **In sum, there's some reason to suspect that Americans might be different from other Westerners, as Tocqueville noted.**

Given the centrality of self-concept to so many psychological processes, it follows that the unusual emphasis on American individualism and independence would be reflected in a wide spectrum of self-related phenomena. For example, self-concepts are implicated when people make choices (e.g., Vohs et al. 2008). While Westerners tend to value choices more than non-

Westerners (e.g., Iyengar & DeVoe 2003), Americans value making choices more still, and prefer more opportunities, than do those from elsewhere (Savani et al. in press). For example, in a survey of people from six Western countries, only Americans would prefer a choice from 50 different ice cream flavors compared with 10 different flavors. Likewise, Americans (and Britons) prefer to have more choices on menus from upscale restaurants than do those from other European countries (Rozin et al. 2006). The array of choices available, and people's motivation to make such choices, are even more extreme in the U.S. compared to the rest of the West.

Likewise, because cultural differences in analytic and holistic reasoning styles appear to be influenced by whether one views the social world as a collection of discrete individuals or as a set of interconnected relationships (Nisbett, 2003), it follows that exceptionally individualistic Americans should be exceptionally analytic as well. One recent study suggests that this might indeed be the case: Americans showed significantly more focused attention in the Framed Line Task than did people from other European countries (Britain and Germany) as well as Japanese (Kitayama et al., 2008). Although more research is needed, Americans may see the world in more analytic terms than the rest of the West.

Terror management theory maintains that because humans possess the conscious awareness that they will someday die, they cope with the associated existential anxiety by making efforts to align themselves with their cultural worldviews (Greenberg et al. 1997). Although the tendency to defend one's cultural worldview following thoughts about death has been found in every country studied thus far, a meta-analysis reveals that the effect sizes are larger among American samples ( $r = 0.41$ ) than among other Western ( $r = 0.29$ ) or non-Western samples ( $r = 0.26$ ; Burke, Martens, & Faucher, n.d.). Curiously, Americans respond more defensively to death thoughts than those from other countries.

In the previous section, we discussed Herrmann et al.'s (2008) work showing substantial differences in punishment between Western and non-Western societies. While Western countries all clump at one end of Figure 4, the Americans anchor the extreme end of the West's distribution. Perhaps it is for this same reason that Americans have the world's highest worker productivity.

## 4.2 Similarities between Americans and Westerners

We are unable to locate any research program (other than the ones reviewed in the first two telescoping contrasts) that has demonstrated that American psychological and behavioral patterns are similar to other Westerners. We reason that there should be many similarities between the US and the rest of the West, and we assume that many researchers share our impression. Perhaps this is why we are not able to find studies that have been conducted to

explicitly establish these similarities—many researchers likely would not see such studies as worth the effort. In the absence of comparative evidence for a given phenomenon it might not be unreasonable to assume that the Americans will look similar to the rest of the West. However, the above findings provide a hint that, at least along some key dimensions, Americans are extreme.

## **5 Contrast 4: Typical Contemporary American Subjects vs. Other Americans**

The previous contrasts have revealed that WEIRD populations frequently occupy the tail-end of distributions of psychological and behavioral phenomena. However, it is important to recognize, as a number of researchers have (Arnett 2008, Medin & Atran 2004, Sears 1986), that the vast majority of behavioral research on non-clinical populations within North America is conducted on undergraduates (Peterson 2001, Wintre et al. 2001). Further, within psychology, the individuals are usually psychology majors, or at least taking introductory psychology courses. In the case of child participants, they are quite often the progeny of high socioeconomic status (SES) people. Thus, there are numerous social, economic, and demographic dimensions that tentatively suggest these subjects might be unusual. But, are they?

### **5.1 Social Psychology**

Highly educated Americans differ from other Americans in many important respects. For a number of the phenomena reviewed above in which Americans were identified as global outliers, highly educated Americans occupy an even more extreme position than less educated Americans. These findings are summarized below:

- 1) Although college-educated Americans have been found to rationalize their choices in dozens of post-choice dissonance studies, Snibbe and Markus (2005) found that non-college educated American adults do not (c.f., Sheth 1970).
- 2) Although Americans are the most individualistic people in the world, American undergraduates score higher on some measures of individualism than do their non-college educated counterparts, particularly for those aspects associated with self-actualization, uniqueness, and locus of control (Kusserow 1999, Snibbe & Markus 2005).
- 3) Conformity motivations were found to be weaker among college-educated Americans than non-college-educated Americans (Stephens et al. 2007), who acted in ways more similar to that observed in East Asian samples (cf., Kim & Markus 1999).

4) Non-college educated adults are embedded in more tightly-structured social networks than are college students (Lamont 2000), which raises the question of whether research on relationship formation, dissolution, and interdependence conducted among students will generalize to the population at large.

5) A large study that sampled participants from the general population in Southeast Michigan found that working class people were more interdependent and more holistic than middle class people (Grossmann et al. 2009)

6) The moral reasoning of college-educated Americans occurs almost exclusively within the ethic of autonomy, whereas non-college educated Americans use the ethics of community and divinity (Haidt et al. 1993, Jensen 1997). Parallel differences exist in moral reasoning between American liberals and conservatives (Haidt 2007).

7) College-students (the vast majority of whom are American) respond with more cultural worldview defense to death thoughts ( $r = .37$ ) than do non-college students ( $r = .24$ ; Burke et al., n.d.).

A second-order meta-analysis ( $N > 650,000$ ,  $K > 7000$ ) of studies that either included college student samples or non-student adult samples revealed that the two groups differed either directionally or in magnitude for approximately *half* of the phenomena studied (e.g., attitudes, gender perceptions, social desirability; Peterson 2001). However, no clear pattern regarding the factors that accounted for the differences emerged. Other research has found that American undergraduates have higher degrees of self-monitoring (Reifman et al. 1989), are more susceptible to attitude change (Krosnick & Alwin 1989), and are more susceptible to social influence (Pasupathi 1999) compared to non-student adults.

## 5.2 Behavioral Economics

Research in behavioral economics indicates substantial differences between undergraduate and non-student adults. For example, in both the Ultimatum and Dictator Games non-student Americans (both rural and urban participants) make significantly higher offers than undergraduate subjects (Henrich & Henrich 2007). The difference is most pronounced in Dictator games in which samples of non-student American adults from Missouri (urban and rural Missouri did not differ) offered a mean 47% of the total stake while undergraduate freshman gave 32%, well within the typical range for undergraduates in this game (Camerer 2003, Ensminger & Cook under review, Henrich & Henrich under review). The seemingly high Missouri non-student adult offers in the Dictator Game are similar to those found in other non-student samples in the U.S. (Carpenter et al. 2005, Henrich & Henrich 2007). Similarly, research comparing students to a representative random sample of adults using the Trust Game and Public Goods contributions show that undergraduates provide a lower bound on prosociality

measures (Bellemare & Kroger 2007, Carpenter et al. 2008). Dictator Game treatments involving double-blind setups, such that the experimenter cannot know how much a subject contributes, have dramatically smaller effects on offers among non-student adults, and sometimes no effect at all in adult populations outside the U.S. (Lesorogol & Ensminger under review). Other studies also show the peculiarity of student subjects vis-à-vis non-students (Bosch-Domenech et al. 2002, Fehr & List 2004, Haigh & List 2005).

Research also indicates that, within the age range of undergraduates, developmental or acculturative some motivational and behavioral changes are still occurring (Henrich 2008). For example, Ultimatum Game offers continue to change over the university years, with freshman making lower offers than seniors (Carter & Irons 1991). Other work shows that in the Ultimatum Game offers do not hit their adult plateau in behavioral games until around age 24 (Carpenter et al. 2005), after which time offers do not change with age until people reach old age. In trust games, measures of trust and trustworthiness increase with age until they reach a plateau, close to age 30 (Sutter & Kocher 2007).

In some domains, there seems to be little difference between undergraduates and real adults (Egas & Riedl 2008), so the problem is not that undergraduates are always different, but that without doing the work we don't know in which domains undergraduates are unusual.

### 5.3 Variation Within Subpopulations of American children

Although studying young children is one important strategy for discerning universals, it does not completely avoid these challenges since developmental studies are frequently biased toward middle- and upper-class American children. Recent evidence indicates that something as seemingly basic as the differences in spatial reasoning between males and females (Hyde 1981, Mann et al. 1990, Voyer et al. 1995) does not generalize well to poor American children. On two different spatial tasks, repeated four times over two years with 547 second and third graders, low SES children did not show the sex differences observed in middle and high SES children from Chicago (Levine et al. 2005). Such findings, when combined with other research indicating no sex differences on spatial tasks among migratory foragers (Berry 1966), suggest that a proper theory of origins of sex differences in spatial abilities needs to explain why both poor Chicago children and foragers do not show any sex differences.

Research on IQ using analytical tools from behavioral genetics has long shown that IQ is highly heritable, and not particularly influenced by shared family environment (Dickens & Flynn 2001, Flynn 2007). However, recent work using 7-year old twins drawn from a wide range of socioeconomic statuses, shows that contributions of genetic variation and shared environment varies dramatically from low to high SES children (Turkheimer et al. 2003). For high SES children, where environmental variability is negligible, genetic differences account for 70-80%

of the variation, with shared environment contributing less than 10%. For low SES children, where there is far more variability in environmental contributions to intelligence, genetic differences account for 0-10% of the variance, with shared environment contributing about 60%. This raises the specter that much of what we think we have learned from behavioral genetics may be misleading, as the data are disproportionately influenced by WEIRD people, and their children (Nisbett 2009). A more complete investigation of heritability demands a comparison of measures across diverse environments and populations.

#### 5.4 Contemporary Americans compared with Previous Generations of Americans

Contemporary Americans may also be psychologically unusual compared to their forebears 50 or 100 years ago. Some documented changes among Americans over the past few decades include increasing individualism, as indicated by an increasingly solitary lifestyle dominated by individual-centered activities and a decrease in group-participation (Putnam 2000), and a lower need for social approval (Twenge & Im 2007). Again, these findings suggest that the unusual nature of Americans in these domains, as we reviewed earlier, may be a relatively recent phenomenon. These findings raise doubts as to whether research on contemporary American students (and WEIRD people more generally) is even extendable to American students of previous decades.

The evidence of temporal change is probably best for IQ. Research by Flynn (1987, 2007) shows that IQ scores increased over the last half century by 18 points in all industrialized nations for which there were adequate data. Moreover, this rise was driven primarily by increasing scores on the *analytic* subtests. This is a striking finding considering recent work showing how unusual Westerners are in their analytic reasoning styles. Given such findings, it seems plausible that Americans of only 50 or 100 years ago were reasoning in ways much more similar to the rest of the non-Western world than Americans of today.

#### 5.5 Similarities between typical contemporary experimental subjects vs. other Americans

We expect that typical American subjects are very similar to other Americans in myriad ways. The problem with this expectation, however, is that it is not immediately apparent in which domains they should be similar. We think that there are enough differences between these two groups to raise concerns about speaking incautiously on the thoughts and behaviors of Americans, in general. There have been rather few studies that have explicitly contrasted whether undergraduates or college-educated Americans differ in various psychological measures from those who are not currently students, or who were never college-educated. There are numerous meta-analyses that include data from both college student and non-

student samples that speak partially to this issue. Although the meta-analyses do not specify the national origin of the participants, we assume that most of the subjects were American. Some of these analyses indicate considerable similarity between student and non-student samples. For example, the aforementioned second-order meta-analysis (Peterson 2001) revealed similarities between students and non-student samples for about half of the phenomena. Similarly, the relation between attribution styles and depression (Sweeney et al. 1986), and the relations among intentions, attitudes, and norms (Farley et al. 1981) do not show any appreciable differences between student and non-student samples. In these instances, there do not appear to be any problems generalizing from student to non-student samples, which may suggest that college-education, and SES more generally, are not related to these phenomena.

## 5.6 Summary of Contrast 4

Numerous findings from multiple disciplines indicate that, in addition to numerous similarities, there are differences among typical subjects and the rest of the American population in unexpected domains. In some of these domains (e.g., individualism, moral reasoning, worldview defense in response to death thoughts, and perceptions of choice) the data from American undergraduates represent even more dramatic departures from the patterns identified in non-Western samples. Further, contemporary American college students appear further along some of these dimensions than did their predecessors a few decades earlier.

**Typical subjects may be outliers within an outlier population.**

## 6 General Discussion

As the four contrasts summarized above reveal, WEIRD subjects are unusual in the context of the world in some key ways. In this section we first discuss the main conclusions and implications of our empirical review. We then address two common challenges to our claim that WEIRD subjects are frequent outliers. Finally, we make some recommendations for how the behavioral sciences may address these challenges.

### 6.1 Summary of Conclusions and Implications

#### 6.1.1 Pronounced Population Variation is Commonplace in the Behavioral Sciences.

There are now enough sources of experimental evidence, using widely differing methods from diverse disciplines, to indicate that there is substantial psychological and behavioral variation among human populations. The reasons that account for this variation may be manifold, including behavioral plasticity in response to different environments, divergent trajectories of cultural evolution, and, perhaps less commonly, differential distribution of genes across groups

in response to different selection pressures. We think the existence of this population-level variation alone should suffice to energize course corrections in our research directions.

At the same time, we have also identified many domains in which there are striking similarities across populations. These similarities could indicate reliably developing pan-human adaptations, byproducts of innate adaptations (such as religion), or independent cultural inventions or cultural diffusions of learned responses that have universal utility (such as counting systems, or calendars). We have no doubt that there are many more cross-population similarities than we have mentioned (e.g., our taste for sugar or the capacity of short-term memory); however, thus far there are few databases sufficient to evaluate the similarities or differences across populations.

Many of the processes identified above that vary dramatically across populations would seem to be “basic” psychological processes. The reviewed findings identified variation in aspects of visual perception, memory, attention, fairness motivations, folkbiological categorization and induction, spatial reasoning, self-enhancement, moral reasoning, defensive responses to thoughts about death, and heritability estimates of IQ. These domains do not appear to be any less “fundamental” than those domains for which much similarity has been identified. At this point we know of no strong grounds to make *a priori* claims to the “fundamentality” of a given psychological process. A worthy goal is to develop theories that predict which elements of our psychological processes are reliably developing and which are locally variable, and under what conditions (Barrett 2006).

The application of evolutionary theory does not provide grounds for such *a priori* claims of “fundamental” or “basic” processes, at least in general. Evolutionary theory is a powerful tool for generating and eliminating hypotheses. However, despite its power, it is often overly fecund, as it generates multiple competing hypotheses, with predictions dependent on unknown aspects of ancestral environments. Adjudicating among alternative evolutionary hypotheses often requires comparative work. Moreover, theoretical work is increasingly recognizing that natural selection has favored ontogenetic adaptations that allow humans, and other species, to adapt epigenetically to local environments (Henrich 2008).

### 6.1.2 *WEIRD subjects may often be the worst population from which to make generalizations.*

The empirical foundation of the behavioral sciences comes principally from experiments with American undergraduates. The patterns we have identified in the available (albeit limited) data indicate that this sub-subpopulation is highly unusual along many important psychological and behavioral dimensions. It is not merely that researchers frequently make generalizations from a narrow subpopulation. The concern is that this particular subpopulation is highly

*unrepresentative* of the species. The fact that WEIRD people are the outliers in so many key domains of the behavioral sciences renders them—perhaps—one of the worst subpopulations one could study for generalizing about *Homo sapiens*.

To many anthropologically-savvy researchers it is not surprising that Americans, and people from modern industrialized societies more generally, appear unusual vis-à-vis the rest of the species. For the vast majority of its evolutionary history, humans have lived in small-scale societies without formal schools, governments, hospitals, police, complex divisions of labor, markets, militaries, formal laws, or mechanized transportation. Every household provisioned much or all of their own food, made its own clothes, tools, and shelters, and—aside from various kinds of sexual divisions of labor—almost everyone had to master the same skills and domains of knowledge. Children grew up in mixed age play-groups, received little active instruction, and learned largely by observation and imitation. By age 10, children in some foraging societies obtain sufficient calories to feed themselves, and adolescent females take on most of the responsibilities of women. WEIRD people, from this perspective, grow up in, and adapt to, a highly unusual environment. It should not be surprising that their psychological world is unusual as well.

### *6.1.3 Research Topics have been Limited by the Heavy Reliance on WEIRD Populations.*

Relying on WEIRD populations may cause researchers to miss important dimensions of variation, and devote undue attention to behavioral tendencies that are unusual in a global context. There are good arguments for choosing topics that are of primary interest to the readers of the literature (i.e., largely WEIRD people); however, if the goal of the research program is to shed light on the human condition, then this narrow unrepresentative sample may lead to an uneven and incomplete understanding. We suspect that some topics such as conformity, cognitive dissonance, fairness, and analytic reasoning might not have been sufficiently interesting to justify in-depth investigation for most humans at most times throughout history. Alternatively, the behavioral sciences have shown a rather limited interest in such topics as family, food, ethnicity (not race), religion, sacred values, sacrifice, and rituals (see Rozin 2001 for further critiques on this point, Rozin et al. 2006). Had the behavioral sciences developed elsewhere, important theoretical foci and central lines of research would likely look very different (Medin & Bang 2008).

### *6.1.4 Studying Children and Primates is Crucial, But not a Replacement for Comparative Work*

Working with children and non-human primates is essential for understanding human psychology. However, it is important to note that despite its great utility and intuitive appeal, such research does not fully obviate these challenges. First, in the case of primate research, discovering parallel results in great apes and in one human population is an important step, but

it doesn't tell us how reliably developing a particular aspect of psychology is. As the spatial cognition work indicates, since language and cultural practices can—but need not—influence the cognition we acquired from our phylogenetic history as apes, then establishing the same patterns of cognition in apes and Westerners is insufficient to make any strong claims about universality. Suppose most psychologists were Hai\om speakers (instead of Indo-European speakers), they might have studied only Hai\om-speaking children and adults, as well as non-human apes, and concluded (incorrectly) that allocentric spatial reasoning was universal. Similarly, imagine if Tsimane economists compared Ultimatum Game results for Tsimane adults to chimpanzees (Gurven 2004, Henrich & Smith 2001, Jensen et al. 2007). These researchers would have found the same results for both species, and concluded that standard game theoretic models (assuming pure self-interest) and evolutionary analyses (Nowak et al. 2000) were a fairly accurate predictors in Ultimatum Game behavior for both chimpanzees and humans—a very tidy finding. In both of these cases, the conclusions would be opposite to those drawn from studies with WEIRD populations.<sup>11</sup>

Second, studying children is crucial for developing universal theories. However, evidence suggests that psychological differences among populations can emerge relatively early in children (as with folkbiological reasoning), and sometimes differences are even larger in children than in adults, as with the Mueller-Lyer Illusion. Moreover, developmental patterns may be different in different populations, as with sex differences in spatial cognition between low income vs. middle and high income subpopulations in the U.S., or with performance in the false belief task. This suggests a need for converging lines of research. The most compelling conclusions regarding universality would derive from comparative work among diverse human populations with both adults and with children, including infants if possible. Human work can then be properly compared with work among non-human species (including but not limited to primates), based on a combination of field and laboratory work.

### *6.1.5 Understanding Human Diversity is Crucial for Constructing Evolutionary Theories of Human Behavior.*

Evolution has equipped humans with ontogenetic programs, including cultural learning, that help us adapt our bodies and brains to the local physical and social environment. Over human history, convergent forms of cultural evolution have effectively altered our physical environments with tools, technology, and knowledge; our cognitive environments with counting systems, color terms, written symbols, novel grammatical structures, categories, and heuristics; and our social environments with norms, institutions, laws, and punishments. Broad patterns of psychology may be—in part—a product of our genetic program's common response to culturally-constructed environments that have emerged and converged over thousands of years. This means the odd results from small-scale societies, instead of being dismissed as

unusual exceptions, ought to be considered as crucial data points that help us understand the ontogenetic processes that build our psychologies in locally adaptive and context-specific ways.

Based on this and the previous point, it seems clear that comparative developmental studies involving diverse human societies combined with parallel studies of non-human primates (and other relevant species) provide an approach to understanding human psychology and behavior that can allow us to go well beyond merely establishing universality or variability. Such a systematic multi-pronged approach can allow us to test a richer array of hypotheses about the processes by which both the reliable universal patterns and the diversity of psychological and behavioral variation emerge.

### *6.1.6 Exclusive Use of WEIRD Samples is Sometimes Justified.*

Our argument should not be construed to mean that the exclusive use of WEIRD samples should always be avoided. There are cases where exclusive use of these samples would be legitimate (Mook 1983). One such example is research programs that are seeking existential proofs for psychological or behavioral phenomena (e.g., Fehr & Gächter 2002). That is, if the question is whether a certain phenomenon can be found in humans at all, reliance on *any* slice of humanity would be a legitimate sampling strategy. For example, the work of Tversky, Kahneman, and their colleagues sought to demonstrate the existence of systematic biases in decision making that violates the basic principles of rationality assumed to be true everywhere (Gilovich et al. 2002). Most of their work was done with WEIRD samples. That counterexamples to rational behavior could be found in *any sample* in the world was an important discovery that does not hinge on generalizability. Nevertheless, even in such cases, learning about the extent to which population variability affects such phenomena is a necessary subsequent phase of the enterprise, since any theory of human behavior ultimately has to account for such variability (if it exists).

## **6.2 Concerns with our argument**

We have encountered two quite different sets of concerns about our argument. Those with the first set of concerns, elaborated below, worry that our findings are exaggerated because (a) we may have cherry-picked only the most extreme cases that fit our argument, and have thus exaggerated the degree to which WEIRD people are outliers, and/or (b) the observed variation across populations may be due to various methodological artifacts that arise from translating experiments across contexts. The second concern is quite the opposite: some researchers dismissively claim that we are making an obvious point, which everyone already recognizes. Perhaps the most productive thing we offer is for these two groups of readers to confront each other.

We preface our response to the first concern with an admonition: of course, many patterns and processes of human behavior and psychology will be generally shared across the species. We recognize that human thought and behavior is importantly tethered to our common biology and our common experiences. Given that many human universals exist, the real challenge is to design a research program that can explain their evolution, development and variation.

We offer three general responses to the concern that our review presents a biased picture. To begin, we constructed our empirical review targeting studies involving important psychological or behavioral concepts which were, or still are, considered to be universal, and that have been tested across diverse populations. We also listed and discussed major comparative studies that have identified important cross population similarities. Since we have surely overlooked relevant material, we invite commentators to add to our efforts in identifying phenomena which have been widely tested across diverse subpopulations.

Second, we acknowledge that since proper comparative data is lacking for most studied phenomena, we cannot accurately evaluate the full extent of how unusual WEIRD people are. This is, however, *precisely the point*. We hope research teams will be inspired to span the globe and prove our claims of non-representativeness wrong. The problem is that we simply do not know how well many key phenomena generalize beyond the extant database of WEIRD people. The evidence we present aims only to challenge (provoke?) those who assume undergraduates are sufficient to make claims about human psychology and behavior.

Third, to address the concern that the observed population-level differences originate from the methodological challenges of working across diverse contexts, we emphasize that the above evidence derives from diverse disciplines, theoretical approaches, and methodological techniques. They include experiments involving 1) incentivized economic decisions; 2) perceptual judgments; 3) deceptive experimental practices that prevented subjects from knowing what was being measured; and from 4) children, who are less likely than adults to have motivations to shape their responses in ways that they perceive are desirable (or undesirable) to the experimenter. These findings, often published in the best journals of their respective fields, hinged on the researchers making a compelling case that their methodology was comparably meaningful across the populations being studied.

Furthermore, the same methods that have yielded population differences in one domain have demonstrated similarities in other domains (Atran 2005, Haun, Rapold et al. 2006, Henrich & McElreath 2002, Henrich et al. 2006, Herrmann et al. 2008, Norenzayan, Choi et al. 2002, Segall et al. 1966). If one wants to highlight the demonstrated similarities, one cannot then ignore the demonstrated differences which relied on the same or similar methodologies.

Note also that few of the findings that we reviewed involved self-report measures, for which there are well-known challenges in making cross-cultural comparisons across means (Chen et al. 1995, Hamamura et al. 2008, Heine et al. 2002, Peng et al. 1997). Thus, while methodological challenges may certainly be an issue in some cases, we think it strains credulity to suggest that such issues plague all comparative studies we reviewed, and thus can eliminate our concerns about the non-representativeness of typical subjects.

### 6.3 Recommendations

Our experience is that most researchers who work exclusively with WEIRD subjects would like to establish the broad generalizability of their findings. Even if they strongly suspect that their findings will generalize across the species, most will agree that it would be better to have comparative data across diverse populations. The problem, then, is not principally a scientific or epistemological disagreement, but one of institutionalized incentives. Hence, addressing this issue will require adjusting the existing incentive structures for researchers. The central focus on these adjustments should be that in presenting our research designs to granting agencies, or our empirical findings in journals, we must explicitly address the questions of generalizability and representativeness. With this in mind, we offer the following recommendations.

Journal editors and reviewers should press authors to both explicitly discuss and defend the generalizability of their findings. Claims and confidence regarding generalizability must scale with the strength of the empirical defense. If a result is novel, being explicitly uncertain about generalizability should be fine, but one should not imply universality without an empirically-grounded argument.

This does not imply that all experimentalists need to shift to performing comparative work across diverse subject pools! As comparative evidence accumulates in different domains, researchers will be able to assess the growing body of comparative research and thus be able to calibrate their confidence in the generalizability of their findings. The widespread practice of subtly implying universality by using statements like “people’s reasoning is biased...” should be avoided. “Which people?” should be a primary question for reviewers. We think this practice alone will energize more comparative work.

The experience of evolutionary-oriented researchers attests to the power of such incentives. More than other researchers in the social sciences, evolutionary researchers have led the way in performing systematic comparative work, drawing data from diverse societies. This is not because they are interested in variation per se (though some are), but because they are compelled, through some combination of their scientific drive and the enthusiasm of their critics, to test their hypotheses in diverse populations (e.g., Billing & Sherman 1998, Buss 1989,

Daly & Wilson 1988, Fessler et al. 2005, Gangestad et al. 2006, Kenrick & Keefe 1992a;1992b, Low 2000, Medin & Atran 2004, Schaller & Murray 2008, Schmitt 2005, Sugiyama et al. 2002).

Meta-analyses are often compromised because many studies provide little background information about the subjects. Journal editors should require explicit and detailed information on subject pool composition. Some granting agencies already require this. Comparative efforts would also be greatly facilitated if researchers would make their data readily available to any who asked, or, better yet, data files should be made available online. Sadly, a recent investigation found that only 27% of authors in psychology journals shared their data when an explicit request was made to them in accordance with APA guidelines (Wicherts et al. 2006). Tests of generalizability require broad access to published data.

Given the general state of ignorance with regard to the generalizability of so many findings, we think granting agencies, reviewers, and editors would be wise to give researchers credit for tapping and comparing diverse subject pools. Work with undergraduates and the children who live around universities is *much* easier than going out into the world to find subjects. As things stand, researchers suffer a competitive disadvantage when seeking a more diverse sampling of subjects. Because many of the best journals routinely require that papers include several studies to address concerns about internal validity (Carver 2004), the current incentives greatly favor targeting the easiest subject pool to access. There is an often unrecognized tradeoff between the experimental rigor of using multiple studies and the concomitant lack of generalizability that easy-to-run subject pool studies entail. If the incentive structure came to favor non-student subject pools, we anticipate that researchers could also be more persuasive in encouraging their universities and departments to invest in building non-student subject pools, for example by setting up permanent psychological and behavioral testing facilities in bus terminals, rail stations, airports, and anywhere diverse subjects might find themselves with extra time.

Beyond this, departments and universities should build research links to diverse subject pools. There are literally untapped billions of people around the world who would be willing to participate in research projects, as both paid subjects and research assistants. The amounts of money necessary to pay people who might normally make less than \$12 per day are trivial vis-à-vis the average research grant. Development economists, anthropologists and public health researchers already do extensive research among diverse populations, and thus already possess the contacts and collaborations. Experimentalists merely need to work on building the networks.

Funding agencies, departments, and universities can encourage and facilitate both professors and graduate students to work on expanding sample diversity. Research partnerships with non-WEIRD institutions can be established to further the goal of expanding and diversifying the

empirical base of the behavioral sciences. By supplying research leaves, adjusted expectations of student progress, special funding sources, and institutionalized relationships to populations outside the university as well as to non-WEIRD universities, these organizations can make an important contribution to building a more complete understanding of human nature.

### Closing Words

While we are certainly not the first to worry about the representativeness of undergraduates (Gergen 1973, Medin & Atran 2004, Norenzayan & Heine 2005, Rozin 2001, Sears 1986, Sue 1999) our efforts to compile an empirical case has revealed an even more alarming situation than previously recognized. The sample of contemporary Western undergraduates that so overwhelms our database is not just an extraordinarily restricted sample of humanity; it is frequently a distinct outlier vis-à-vis other global samples. It may represent the worst population on which to base our understanding of *Homo sapiens*. Behavioral scientists now face a choice – they can either acknowledge that their findings in many domains cannot be generalized beyond this unusual subpopulation (and leave it at that), or they can begin to take the difficult steps to building a broader, richer and better-grounded understanding our species.

### Endnotes

<sup>1</sup> We also use the term “WEIRD” throughout this paper to refer to the exceptional nature of this sample, and do not intend any negative connotations or moral judgments by the acronym.

<sup>2</sup> Rivers, for instance, found that cultures with a single color term for blue and green could still tell the difference between a blue and a green thread.

<sup>3</sup> Fessler also emphasizes important differences in shame and guilt between American and Indonesians.

<sup>4</sup> To illustrate the limits of inferring universality from two-culture comparisons we note the finding that field independence on the Rod and Frame task is shown both for migratory foragers and Americans (Witkin & Berry 1975), yet East Asians and sedentary foragers show evidence for field dependence (Ji et al. 2000).

<sup>5</sup> We are using “Western” to refer to those countries clustered in the north-west of Europe (U.K. France, Germany, Switzerland, the Netherlands, etc.), and British-descent societies such the U.S. Canada, New Zealand, and Australia. In particular, we are concerned about those populations from which most subjects in behavioral and psychological experiments are drawn. We recognize that there are important limitations and problems with this label, but we use it for convenience.

<sup>6</sup> See also Knowles et. al. (2001); but, for contrary findings see Lieberman, Jarcho, & Obayashi (2005).

<sup>7</sup> Interestingly, evidence indicates a somewhat different pattern in small-scale societies, see Marlowe (2004), Moore et al. (2006), and Pillsworth (2008).

<sup>8</sup> Efforts to replicate these findings in various small-scale societies have failed (Marlowe & Wetsman 2001, Sugiyama 2004, Yu & Shepard 1998). These failures suggest a more complicated, and context-specific, set of evolutionary hypotheses (Marlowe et al. 2005, Swami & Tovée 2007).

<sup>9</sup> The robustness of the Five Factor Model is considerably weaker when it is derived from indigenous personality traits from other languages, although some of the five traits do still emerge (Benet-Martinez & Waller 1995, Cheung et al. 1996, Saucier et al. 2005).

<sup>10</sup> Our WEIRD acronym unfortunately does not include an A for Americans; “Rich” and “Democratic” refer to this population.

<sup>11</sup> These examples illustrate a parallel problem for those interested in the differences between human and non-human cognition. Since most ape-human comparisons involve WEIRD people (or their children) as subjects, some seeming ape-human differences may not represent real species-level contrasts, but may instead reflect the psychological peculiarities of WEIRD people (Boesch 2007).
